ABSTRACT

ASCA and *ROSAT* data of the Centaurus cluster, holding a cD galaxy NGC 4696, were analyzed, as a partial re-analysis after Fukazawa et al. (1994), Fabian et al. (1994), and Allen & Fabian (1994). Radial brightness profiles in different energy bands show that the central excess emission of this cluster, known previously in soft X-rays (< 4 keV), is present also in the hard energy band up to 10 keV. Therefore the central excess emission cannot be explained solely by a temperature drop together with a King-type potential having a flat core, and requires a deeper central potential. A double- β brightness distribution gives a good account of the data. A deprojected energy spectrum within a spherical region of radius ~ 30 kpc at the cluster center indicates that the ICM cannot be isothermal there. Simultaneous fitting of the three (PSPC, GIS, and SIS) energy spectra extracted from the central region within a projected radius of 3 arcmin showed that a two-temperature model that has temperatures of 1.4 keV and 4.4 keV and a common metallicity of 1.0 solar with the Galactic absorption gives the best description to the spectra. A cooling-flow spectral model did not give satisfactory fit. These results reconfirm the two-phase picture developed by Fukazawa et al. (1994) in which the hot ICM fills nearly the entire cluster volume, wherein a small amount of cooler plasma is intermixed and localized near the cluster center. A 3-dimensional cluster model incorporating the two-phase picture, the double- β brightness distribution, and the central metallicity increase reproduced the overall *ASCA* and *ROSAT* data successfully. The spatial distribution of the dark matter that is derived by subtracting the stellar mass from the calculated total-gravitating mass deviates from a King-type profile and exhibits a central excess. Another two-phase cluster model in which the dark-matter density profile is given with the *universal density profile* (Navvaro, Frenk, & White 1996,1997) also gave a satisfactory account to the data. A detailed comparison of the iron mass distribution with that of the stellar component reveals that the iron is more widely spread than stars, which may have been caused by energetic supernovae and the motion of the cD galaxy. Since the derived characteristics of the cool phase including the temperature, angular extent, gas mass, and metallicity, are on a smooth extension of those of inter-stellar medium (ISM) of elliptical galaxies, the cool phase can be regarded as the ISM associated with the cD galaxy, while the high X-ray luminosity of the cool phase (1.1×10^{43} ergs s $^{-1}$ in 0.5–4.0 keV) is interpreted as a result of a compression by the surrounding hot phase. The cool-phase X-ray emission is presumably sustained by energies dissipated by infalling mass to the cD galaxy in the course of cluster evolution.

Subject headings: galaxies:clusters:individual(Centaurus) — inter galactic medium — X-rays:galaxies

1. Introduction

A central dominant galaxy (cD galaxy) is frequently found at the center of a galaxy cluster. Previous imaging X-ray observations revealed that X-ray emission from intra-cluster medium (ICM; e.g. Sarazin 1988) often exhibits strongly peaked brightness, which coincide with cD galaxies (e.g. Jones & Forman 1984). Such clusters can be classified as XD clusters (Jones & Forman 1984) or cD clusters. This phenomenon has generally been interpreted in terms of a temperature gradient in the ICM, particularly due to cooling flows (CF; see Fabian 1994 for a review) occurring at the densest part of the ICM where the radiative cooling time is considerably shorter than the Hubble time. Due to limited spectroscopic capabilities of pre-*ROSAT* instruments, however, the radial temperature profiles of the ICM were usually estimated indirectly from the observed X-ray brightness profiles, assuming a hydrostatic equilibrium of the ICM within a plausible shape of the gravitational potential (i.e. deprojection method; Fabian et al. 1981). Results of such calculations indicate that the ICM temperature often decreases towards the center, typically down to ~ 1 keV. The existence of such a cool component was spectroscopically confirmed with the *Einstein* SSS and FPCS (Canizares et al. 1979; Mushotzky et al. 1981; Lea et al. 1982; White et al. 1994). In addition, excess absorption was observed with the *Einstein* SSS from central regions of a number of cD clusters (White et al. 1991; Johnstone et al. 1992). With the advent of *ROSAT* (Trümper 1984), the temperature gradient decreasing towards the cluster center have been detected in many cD clusters (e.g. Allen et al. 1993).

In reality, the ICM temperature structure is thought to be quite multi-phased, in such a way that there exist many temperatures and densities at a given radius (e.g. inhomogeneous cooling flows; Nulsen 1986). Actually, such a multi-phase structure was suggested in the central region of the Virgo cluster, through fine-resolution spectroscopy with the *Einstein* FPCS (Canizares et al. 1982). Nevertheless, single-phase approximations, in which a single temperature is assigned to each radius, have been used extensively as an approximation. This description has successfully explained the observed data, at least in energy bands below 3 keV, yielding results consistent with those from a multi-phase modeling (Thomas, Fabian, & Nulsen 1987). However, the single-phase approximation may no longer be valid in higher energy ranges, and may fail to reveal some important aspects of cD clusters.

Another key issue related to the central regions of clusters is spatial distribution of the ICM metallicity, which directly reflects the evolutionary history of the cluster and its member galaxies. Koyama, Takano, & Tawara (1991), through scanning observations of the Virgo cluster with the *Ginga* observatory, showed that the iron abundance of the ICM clearly increases towards its cD galaxy, M87. White et al. (1994), utilizing the different sizes of fields of view of the *Einstein* SSS and the *Ginga* LAC, revealed the central metal concentration in A496, A2142, and possibly in A1795 and A2199. However, metallicity gradients in other clusters remained unknown or inconclusive (e.g. for the Perseus cluster; Mushotzky et al. 1981; Ponman et al. 1990; Kowalski et al. 1993; Arnaud et al. 1994). This issue was rather hard to explore even with *ROSAT*, because of the limited spectral resolution and the limited energy band (0.1–2.4 keV) that does not cover the Fe-K line energy (6–7 keV).

The *ASCA* observatory (Tanaka, Inoue, & Holt 1994), with its superior imaging spectroscopic capability up to 10 keV, has drastically improved our knowledge on the

issues of temperature structure and metallicity distribution in ICM. Among many clusters so far observed with *ASCA*, the Centaurus cluster (Cen cluster for short) is of particular interest: it exhibits both the metallicity concentration and the central cool emission in a most outstanding manner, as already reported by Ohashi et al. (1994), Fukazawa et al. (1994; hereafter FEA94), and Fabian et al. (1994; hereafter FABT94). The phenomena are so fascinating that they deserve a still more detailed investigation.

We have hence re-analyzed the previously and the newly obtained *ASCA* data of the Cen cluster, together with those from the *ROSAT* PSPC having a better angular resolution. For the *ASCA* data analysis, we have taken fully into account the complex response of the X-Ray Telescope (XRT; Serlemitsos et al. 1995; Tsusaka et al. 1995; Takahashi et al. 1995) on board *ASCA* using the method described in Ikebe et al. (1997). We have reconfirmed the conclusion made by FEA94, that the ICM in the central region of the Cen cluster is made up of hot and cool phases, and investigated their detailed characteristics. In section 2, we briefly review past X-ray results on the Cen cluster, and point out relevant scientific issues. Section 3 gives a brief description of the *ASCA* and *ROSAT* observations. Results of the new analysis are presented in sections 4 through 6, followed by discussion in section 7. We assume $H_0 = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$ throughout.

2. Previous X-ray Results and Scientific Issues

The Cen cluster, or A3526, is a relatively poor cluster of galaxies (e.g. Dickens, Currie, & Lucey 1986) at a redshift of $z = 0.0104$. It is one of the nearest and the most well studied Abell clusters. At the cluster center, there exists a cD galaxy NGC 4696. The Cen cluster has been observed repeatedly in X-rays, with *Uhuru* (Giacconi et al. 1972; Forman et al. 1978), *HEAO-1* (Mitchell & Mushotzky 1980), the *Einstein Observatory* (Matilsky, Jones, & Forman 1985; David et al. 1993), *EXOSAT* (Edge & Stewart 1991), and *Ginga* (Yamashita 1992). These observations indicate the 2–10 keV luminosity of $7 \times 10^{43} \text{ erg s}^{-1}$, and the ICM temperature of $\sim 4 \text{ keV}$ except in the central region. A central excess brightness, interpreted as a CF, was detected within $6'$ of the center (Matilsky et al. 1985; Edge & Stewart 1991).

Allen & Fabian (1994; hereafter AF94) analyzed the radius-sorted *ROSAT* PSPC spectra of the Cen cluster, and found that the projected ICM temperature significantly decreases within $\sim 6'$ of the cluster center, where they also found some evidence for increased metallicity or excess absorption. A single-phase deprojection solution derived by AF94 implies that the ICM temperature starts decreasing from $\sim 3.8 \text{ keV}$ at a radius of $\sim 6'$, roughly as $\propto R^{0.5}$ as a function of the three-dimensional radius R , reaching $\sim 1 \text{ keV}$ at the cluster center. They derived a mass deposition rate of $30\text{--}40 M_\odot \text{ yr}^{-1}$.

Subsequently, the Cen cluster was observed with *ASCA*. The *ASCA* spectra within a central $\sim 8'$ region cannot be fit with a single temperature model, requiring at least two temperatures of $\sim 4 \text{ keV}$ and $\sim 1 \text{ keV}$ (Ohashi et al. 1994; FEA94; Ikebe 1995). FABT94 analyzed the spectrum from the central region of the Cen cluster obtained in the same observation, and spectroscopically estimated the mass deposition rate to be $15\text{--}20 M_\odot \text{ yr}^{-1}$ in terms of homogeneous-CF approximation. Thus, the available X-ray data consistently indicate presence of the cool region at the center of the Cen cluster. The *ASCA* data also revealed a drastic metallicity increase towards the center (Ohashi et al. 1994; FEA94; Ikebe 1995). This occurs within $\sim 8'$ of the cD galaxy NGC 4696

and spatially coincides with the appearance of the cooler component. The *ASCA* data of the Virgo cluster also show qualitatively similar temperature and metallicity profiles (Matsumoto et al. 1996).

Based on these new results, FEA94, Makishima (1994), and Ikebe (1995) developed a two-phased modeling of the ICM, wherein a cool component is confined within $\sim 5'$ of the center, immersed in a hot component that fills the entire cluster volume. This view is apparently supported by the fact that the two temperatures, ~ 4 keV and ~ 1 keV, are quite constant as a function of the projected radius from the center (FEA94; Ikebe 1995). However, an X-ray spectrum involving many temperature components, such as is implied by a single-phased ICM after projection, or by inhomogeneous CFs, may well be approximated with just two model temperatures (FABT94). In addition, the apparent existence of the hot emission at the cluster center might be an artifact caused by the complex responses of the XRT on board *ASCA*. In short, the true three-dimensional temperature structure of the ICM in the central region of this cluster is still unknown.

3. Observation and Data Selection

3.1. *ASCA* observations

The Cen cluster was observed twice with *ASCA*, in 1993 and 1995. The observation log is given in Table 1, and the pointing positions are shown in Figure 1a.

The 1993 observation took place during the PV (performance verification) phase. Because the X-ray emission from the Cen cluster extends beyond edge of the $25'$ -radius field of view of the *ASCA* GIS (Gas Imaging Spectrometer; Ohashi et al. 1996; Makishima et al. 1996a), three separate pointings were made; one right on the cluster center, and the others with $18'$ offset from the cluster center. These data were already used by FEA94, FABT94 and Ikebe (1995). The 1995 observation was performed in the AO-3 period, by pointing on the cluster center for about 59 ksec.

In these observations, the two GIS detectors, GIS2 and GIS3, were operated in the normal PH mode (Ohashi et al. 1996). The two detectors of the SIS (Solid State Imaging Spectrometer) instrument, SIS0 and SIS1, were operated in 4CCD BRIGHT mode during the 1993 observation, while in 1CCD FAINT mode during the 1995 observation. In the following data analysis, we use the GIS data (§4, §5 and §6), as well as a limited portion of the SIS data (§5).

3.2. Selection of the *ASCA* data

We discarded the GIS and SIS data that were taken when the XRT view direction was within $5^\circ.0$ of the local horizon. This is to avoid the periods when the target is earth occulted, and to exclude the effect of solar X-rays scattered off the atmosphere. Additional screening that the elevation angle from the sunlit earth is greater than 25° and 20° was applied to the SIS0 and SIS1 data, respectively. In order to ensure a low and stable particle background, we also discarded the GIS and SIS data acquired under geomagnetic cutoff rigidity smaller than 6 GeV c^{-1} .

The background is composed of cosmic X-ray background (CXB) and non X-ray background (NXB). The CXB component was derived from the data of blank-sky observations performed in 1993 and 1994. We estimated the NXB component by using the data taken when the XRT is pointing at the dark (night) earth. Detailed description of the *ASCA* background properties, and the method of background subtraction, are found in Kubo et al. (1994), Ikebe et al. (1995), Ueda et al. (1996), and Ishisaki et al. (1997).

By analyzing the *ASCA* data taken in 1995, we found that the X-ray peak position is systematically displaced by $\sim 0.6'$ from that measured in 1993. This is most probably due to inaccuracy in the satellite attitude determination (see Gotthelf 1996). In order to eliminate the discrepancy, we have adjusted the individual photon positions of the 1995 data so that the peak positions obtained in the two epochs become coincident. This does not affect our results, since we do not discuss absolute alignment X-ray features relative to the optical position, and we are mostly concerned with angular scales larger than $1'$.

Figure 1b shows the 0.7–10 keV GIS image of the Cen cluster obtained in this way. Data from the two GIS detectors are combined, and events from the four partially-overlapping pointings (obtained in 1993 and 1995) are synthesized into a single image after correction for exposure and for the systematic attitude difference mentioned above. The background was subtracted but the image is not corrected for the XRT vignetting. The emission from the cluster is thus detectable up to the boundary of the GIS field of view, exhibiting an approximate circular symmetry around the cD galaxy, which coincides with the X-ray peak.

Although the GIS has sensitivity in the 0.7–10 keV range (Ohashi et al. 1996), its response below ~ 1 keV is still subject to some uncertainties arising from complex xenon M-edge structures. This sometimes causes a noticeable discrepancy between the GIS and SIS spectra around 1 keV. Furthermore the actual GIS image of Cygnus X-1, which is needed in the image analysis with the GIS data, is blurred in soft energies by interstellar grain scattering. As a consequence, the GIS image analysis becomes less reliable below ~ 1.5 keV. Throughout this paper, we hence discard the GIS data below 1.6 keV.

3.3. *ROSAT* observations

In order to complement the limited angular resolution of *ASCA*, we also utilize the *ROSAT* All Sky Survey data and those from pointing observations with the *ROSAT* PSPC. The *ROSAT* All Sky Survey observations over the Cen cluster were performed in January 1991 with an average exposure time of 290 sec. The X-ray emission from the Cen cluster was detected up to at least $90'$ (~ 1.6 Mpc) from the center. Several *ROSAT* pointings onto the Cen cluster were also performed later with the PSPC.

Our analysis of the *ROSAT* surface brightness distribution utilizes the All Sky Survey data, because the X-ray size of the Cen cluster significantly exceeds the PSPC field of view. The All Sky Survey data provide a virtually flat exposure over the whole cluster, and the point-spread function is averaged out to become nearly position independent. These properties of the All Sky Survey data make the analysis relatively simple. In contrast, for the spectral analysis (§ 5) that requires good photon statistics, we use the 7.5 ksec PSPC pointing data taken on 1992 February 2 right on the cluster

center.

4. Analysis of the Radial Brightness Profiles

Previous X-ray imaging observatories were sensitive only to soft X-rays below ~ 4 keV. It is therefore of great importance to investigate X-ray brightness distributions in broader energy bands using the *ASCA* data. Accordingly, we here analyze the radial count-rate profiles obtained with the *ASCA* GIS, in comparison with that from the *ROSAT* PSPC. For the reason described later in §4.2, we do not analyze the SIS data in this section.

4.1. Radial count-rate profiles

By azimuthally averaging the data around the X-ray centroid, we have derived the GIS radial X-ray count-rate profiles. The data from the two GIS detectors (GIS2 and GIS3) obtained in the 4 pointings were all summed up. Figure 2a shows the background-subtracted GIS profiles thus derived in 5 different energy bands, 1.6–2.4, 2.4–4.5, 4.5–6.0, 6.0–7.1, and 7.1–10.0 keV. The lowest energy band is sensitive to the cool component, while the fourth band covers the Fe-K energy region.

To assist the GIS data analysis, we also derived a radial count-rate profile of the *ROSAT* All Sky Survey data, from which we eliminated contaminating point sources. We used the PI channels from 52 to 201, roughly corresponding to an energy range of 0.5–2.0 keV. Figure 3 shows the derived PSPC count-rate profile, which includes the background. Thus, we have altogether six radial profiles, one from *ROSAT* and five from *ASCA*.

4.2. Method of analysis

In order to quantify the derived radial count-rate profiles, we fit them in a “forward” manner. That is, we represent the three-dimensional emissivity distribution of the ICM by a spherically-symmetric numerical model involving a small number of adjustable parameters. The model emissivity is convolved with the image-response matrix (IRM: Ikebe et al. 1997) that represents the vignetting effects and the position- and energy-dependent point-spread function (PSF) of the telescope plus detector system, and then with the energy response matrices of the focal plane instruments. The obtained model prediction, to which the expected background is added, is directly fitted to the observed count-rate profiles. We search for the best-fit model, through minimization of the χ^2 function defined in Ikebe et al. (1997). This approach allows us to fully take into account the known instrumental responses, and provides a particularly powerful analysis method of the *ASCA* data that are subject to the very complex PSF. However, we must carefully choose the initial model in order to obtain meaningful results.

The PSF of the *ASCA* XRT+GIS can be constructed using the actual images of Cygnus X-1 (Takahashi et al. 1995; Ikebe 1995; Markevitch et al. 1996). When fitting the *ASCA* GIS profiles, we apply 2% systematic errors to the model prediction, and 10%

systematic errors to the background intensity. However, Cygnus X-1 is too bright to be observed with the SIS. Consequently the present analysis method is not applicable to the SIS data, and hence we do not analyze the SIS data in this section. As to the PSF for the *ROSAT* All Sky Survey (XRT+PSPC) data, we use the one calculated at 1.0 keV and averaged over the whole PSPC field of view (Hasinger et al. 1994). The energy dependency of the PSF is small, and negligible in the following analysis.

The IRM used here has a size of 102 in the sky-region dimension, both for the GIS and the PSPC. The 102 regions comprise 16 shell regions of $0'.25$ width covering a spherical region within $R = 4'$, where R is three-dimensional radius from the center, and 86 shell regions of $1'$ width covering $R = 4' - 90'$. Thus, we implicitly assume that no X-ray emission comes from outside the maximum radius of $R_{\text{max}} = 90'$ as is justified by the *ROSAT* PSPC image.

4.3. Single- β fits

As the three-dimensional emissivity model, we first try a single- β profile defined as

$$\epsilon(R) = \epsilon_0 \left[1 + \left(\frac{R}{R_c} \right)^2 \right]^{-3\beta}, \quad (1)$$

where R is again the three-dimensional radius, R_c is the core radius, and β is the beta-parameter. The energy spectrum is assumed to be that of thermal X-ray emission from an isothermal plasma of temperature 4.0 keV with a constant metallicity of 0.3 solar, modified by Galactic absorption of $N_{\text{H}} = 8.8 \times 10^{20} \text{ cm}^{-2}$ (Stark et al. 1992). Although this assumption is inconsistent with the significant spectral changes seen from the Cen cluster, its effect is negligible in the present analysis because we here *individually* treat count-rate profiles integrated over relatively narrow energy bands.

We thus fitted the PSPC profile over a range of $r = 0' - 120'$ with the single- β model plus a constant background, where r denotes the projected radius. As presented in Table 2 and Figure 3a, the fit was unacceptable, because of the long-known central excess emission (Matilsky et al. 1985; AF94). By limiting the fit range to $r > 6'$ where the ICM is virtually isothermal (AF94; FEA94), the fit has become acceptable (Table 2, Fig. 3b) with the best-fit model revealing the strong central excess above it. The obtained best-fit parameters (Table 2) are close to those ($R_c = 5' \pm 1'$ and $\beta = 0.45 \pm 0.03$) derived previously by Matilsky et al. (1985), who used the 0.5–3.5 keV *Einstein* IPC data over a narrower range of $r = 6' - 20'$.

Similarly, we fitted the GIS radial count-rate profiles with the single- β model over $r = 0' - 40'$. The results are shown in Table 2 and Figure 2b. Thus, the single- β model failed to reproduce the GIS profiles in the lower four energy bands. The failure is thought to be caused by the central excess emission, because the fit residuals behave qualitatively in the same manner as those in the unacceptable single- β fit to the PSPC profile using the entire radius range. We hence conclude that the strong central-excess emission of the Cen cluster, previously known in X-ray energies below ~ 4 keV, is present in harder energy ranges at least up to 7.1 keV, although the excess may be rather energy dependent.

The GIS radial profile in the highest energy band (7.1–10 keV) was fitted apparently well with a single- β model. However, the obtained β model is unusually flat with

$\beta = 0.44$, and is inconsistent with that derived with the PSPC profile outside $6'$ ($\beta = 0.57$; Table 2). If the 7.1–10 keV brightness profile in the outer cluster region were really flatter than that in 0.5–2 keV, the ICM temperature would rise significantly towards outside, e.g., from 3 keV at $R \sim 10'$ to 5 keV at $R \sim 60'$, and 7 keV at $R \sim 90'$; this disagrees with the previous observational results (AF94; FEA94). Such an unusually flat solution often occurs when we force a single- β model to fit an X-ray radial profile having a strong central excess (Makishima 1995). We hence infer that the central excess emissivity is present even in the highest GIS energy band. This inference is supported by the fact that the single- β solution in 7.1–10 keV has nearly the same shape as those unacceptable models which approximate the 2.4–4.5, 4.5–6.0, and 6.0–7.1 keV profiles, as can be seen in Table 2. If the data statistics were somewhat better, the single- β fit to the 7.1–10 keV GIS profile would have been rejected as well. A further confirmation of these results is presented below.

4.4. Double- β fits

To better quantify the count-rate profiles, we proceed to use a double β -model given as

$$\epsilon(R) = \epsilon_{0,1} \left[1 + \left(\frac{R}{R_{c,1}} \right)^2 \right]^{-3\beta_1} + \epsilon_{0,2} \left[1 + \left(\frac{R}{R_{c,2}} \right)^2 \right]^{-3\beta_2}. \quad (2)$$

Here $\epsilon_{0,1}$, $\epsilon_{0,2}$, $R_{c,1}$, $R_{c,2}$, β_1 , and β_2 are model parameters; the term with suffix 1 (wider β -component) represents the overall cluster emission, while that with suffix 2 (narrower β -component) represents the central excess emission. This model has been applied successfully to the *ASCA* GIS data of the Fornax cluster (Ikebe et al. 1996), the Hydra-A cluster (Ikebe et al. 1997), Abell 1795 (Xu et al. 1998), and NGC 4636 (Matsushita et al. 1998). Furthermore, Mulchaey & Zabludoff (1998) used the same model to quantify the *ROSAT* PSPC count-rate profiles of several galaxy groups.

Like in the previous subsection, the model is assumed to have the energy spectrum for the isothermal plasma of 4.0 keV temperature and 0.3 solar metal abundance. The core radius and beta value of the wider β -component, are fixed at $R_{c,1}=7'.3$ and $\beta_1=0.57$, respectively, as obtained with the $6' - 120'$ PSPC profile, while the other 4 parameters are left free. This procedure is justifiable, because the observed near-isothermality of the ICM emission for $R > 6'$ requires the outer-region emissivity profile to be independent of X-ray energy, although the amplitude of the central excess may be rather energy dependent. Furthermore in our final analysis made in § 6, we let $R_{c,1}$ and β_1 to vary freely.

As summarized in Table 2 and illustrated in Figure 3c and 2c, this double- β model has given acceptable fits to most of the GIS and PSPC count-rate profiles, possibly except in the 1.6–2.4 keV band. The obtained values of $R_{c,2}$ and β_2 are roughly energy independent within rather large errors. In contrast, as shown in Figure 4, we observe a significant energy dependence in relative strength of the central excess emission, or “relative central excess”; this has been calculated in each GIS or PSPC energy band by integrating the flux implied by the narrower β -component and normalizing it to that carried by the wider β -component, both calculated within a sphere of $R = 5'$.

From these results, we conclude that the central excess emission of the Cen cluster

results from a combination of three apparently separate effects. The first is the presence of the spectral cool component (FEA94; FABT94), which causes the prominent increase in the relative central excess below ~ 4 keV. The second effect is the metallicity increase towards the center, which makes the relative central excess significantly higher in the Fe-K energy band than in the adjacent energy ranges. The somewhat worse fit in the 6.0–7.1 keV band is probably due to an additional effect from the metallicity gradient. The last effect is the intrinsic shape of the gravitational potential, which is inferred since the central excess does not vanish in Figure 4 even in the highest energy band, where the former two effects are expected to be negligible.

4.5. Deprojected spectrum at the center

Now that the three-dimensional emissivity distribution, $\epsilon(R)$, has been determined in the PSPC energy band and in the five GIS energy bands in terms of the double- β model, we can calculate a “deprojected” 6-bin X-ray spectrum at any radius R . This is possible because the best-fit double- β model has been determined in each energy band including proper normalization, and the relative normalization between the PSPC and the GIS is known to an accuracy of $\sim 10\%$. In Figure 5, we show the deprojected spectrum in the central spherical region of $R < 1'.5$ (27 kpc). For comparison, theoretically predicted X-ray spectra from thermal plasmas are illustrated in the same figure.

Thus, the deprojected spectrum at the cluster center does not agree with any of the single-temperature model predictions. Above energies of ~ 4 keV the spectrum is as hard as the $T = 4$ keV model, while the data in lower energy bands require contributions from much cooler (e.g. $T \sim 1$ keV) plasmas. Since the projection effects have already been removed, we should conclude that the ICM in the central $1'.5$ region cannot be isothermal: the cluster center volume must be filled with the hot ICM, where there co-exists the cooler plasma. This nicely reconfirms the two-phased modeling adopted by FEA94 and Ikebe (1995), who already found the hot-phase temperature of $T_h \sim 4$ keV and the cool-phase temperature of $T_c \sim 1$ keV. In contrast, the wide-band GIS data are inconsistent with the *ROSAT* deprojection results (AF94) in which the spectrum at the cluster center is approximated by a single-phase emission with $T \sim 1.3$ keV. Evidently, this discrepancy arises because the *ROSAT* PSPC works only below ~ 2 keV.

At this stage, we arrive at the following two important specifications for the forward-method modeling of the Cen cluster ICM: the double- β model to represent spatial properties, and the two-phase picture to express spectroscopic properties. However, we have so far neglected the strong metallicity concentration which was discovered previously (FEA94); this will be taken into account in § 6.

5. Spectral Analysis in the Central Region

In § 4 we have studied the spatial properties of the X-ray emission, and obtained significantly new findings as to the central region of the Centaurus cluster. However we did not fully utilize the spectral information there. Accordingly in this section, we perform a detailed spectroscopic study of the central region by jointly analyzing spectra from the PSPC, the SIS, and the GIS.

5.1. Derivation of the spectra in the cluster center

We accumulated energy spectra from the PSPC, GIS, and SIS, over the central region of $3'$ radius. The energy ranges covered by the PSPC, GIS and SIS are 0.2–2.0 keV, 1.6–10 keV, and 0.5–10 keV, respectively. The *ROSAT* data used here were taken in a pointing observation in 1992, and the *ASCA* data refer to the 1995 observation. The PSPC background was estimated from the same observation in the annular region of $46' - 48'$ from the X-ray peak. The data from the two GIS detectors were combined together, as were those from the two SIS detectors. The GIS and SIS backgrounds were produced as described in § 3, utilizing the blank sky observations and the night earth data. The background-subtracted spectra thus derived are plotted in Fig. 6.

In the previous works by AF92, FEA94, and FABT94, individual spectra from different detectors were fitted separately. In contrast, we fit the three spectra simultaneously, using the XSPEC package (ver. 10.0). This allows us to perform the highest-quality spectroscopy of the ICM in the central region of this important cluster. However to obtain reliable results under rather high data statistics, we need to consider in advance several technical issues, which are described in the next subsection.

5.2. Technical issues in the spectral fitting

As a thermal plasma emission code, we use the Mewe-Kaastra model (Mewe, Gronenschild & van den Oord 1985; Mewe, Lemen, & van den Oord 1986; Kaastra 1992) modified by Liedahl, Osterheld & Goldstein (1995), which is implemented in XSPEC as MEKAL model. We use the fiducial solar abundances (relative to hydrogen in number) given by Anders & Grevesse (1989); He=0.0977, C= 3.63×10^{-4} , N= 1.12×10^{-4} , O= 8.51×10^{-4} , Ne= 1.23×10^{-4} , Mg= 3.80×10^{-5} , Si= 3.55×10^{-5} , S= 1.62×10^{-5} , Ar= 3.63×10^{-6} , Ca= 2.29×10^{-6} , Fe= 4.68×10^{-5} , and Ni= 1.78×10^{-6} . The abundances of Si, S, Ar, Ca, and Fe are left free, while that of Ni is tied to that of Fe. Other elements are assumed to have the solar abundances.

We should here remember a serious problem of the theoretical Fe-L line modeling, as pointed out by several authors including FABT94 and Arimoto et al. (1997). According to Kaastra (1997), even the improved MEKAL model has significant uncertainties. Therefore, we assign 20% systematic errors to each spectral data point in the 0.4–1.6 keV range, as has been employed successfully by Matsushita et al. (1997) in analyzing the *ASCA* spectra of the X-ray luminous elliptical galaxy NGC 4636.

We employ photoelectric absorption model due to the Wisconsin cross section (Morrison & McCammon 1983), which is implemented in XSPEC as WABS model. We fix the redshift for the PSPC data to the optical value of 0.0104, while we leave free those for the GIS and SIS data in order to compensate any possible slight mismatch in their detector gains. The relative normalizations among the three detectors are also left free.

The *ASCA* spectra for extended sources are generally subject to significant flux mixing among different sky regions due to the widely extended PSF of the XRT. However the spectra accumulated over the central $3'$ of the Cen cluster are contaminated by no more than 20% by photons from the sky regions outside, since the brightness profile is so peaked at the center. Furthermore, both the vignetting and the XRT PSF

can be considered as virtually constant across the $3'$ -radius region. Based on these considerations, we calculate the effective area of the *ASCA* XRT by assuming that a point source located at the X-ray peak is being observed.

Finally, a residual uncertainty in the SIS low energy efficiency is known to cause a systematic over estimate of the absorption column density (Dotani et al. 1996; Cappi et al. 1998). Therefore, only for fitting the SIS spectrum, we artificially apply an additional absorption to spectral models by an equivalent hydrogen column density of $3.0 \times 10^{20} \text{ cm}^{-2}$.

5.3. Two-temperature fits

As already shown in § 4 and in the previous works, the ICM in the central region of the Cen cluster cannot be isothermal, but is more likely to consist of two components having different temperatures. Accordingly, we fit the PSPC, SIS and GIS spectra jointly with a two-temperature thermal emission model modified by photo-electric absorption. The metal abundance for each element is assumed to be common to the two components, and the two components are assumed to suffer the common absorption which is left free. Other specifications of the fitting refer to §5.2. Then, the fitting model can be expressed as WABS*(MEKAL+MEKAL) in XSPEC, to which we shall refer as Model 1.

This Model 1 has given an acceptable simultaneous fit, as shown in Table 3 and Figure 7a. However, a noticeable feature remains both in the SIS and GIS residuals at $\sim 1.7 \text{ keV}$ (Figure 7a). Similar residuals have been noticed in the *ASCA* spectra of the Perseus and Virgo clusters (Fukazawa 1997), and may still be caused by the uncertainty in the Fe-L complex modeling. Therefore we have modified Model 1 by adding one artificial narrow Gaussian line at $\sim 1.7 \text{ keV}$, and refer to it as Model 2, which is expressed as WABS*(MEKAL+MEKAL+LINE). Model 2 has given a satisfactory fit (Table 3; Figure 7b) with the line having a center at 1.74 keV and an equivalent width of 18 eV . The obtained absorption column density is consistent with the Galactic value ($8.8 \times 10^{20} \text{ cm}^{-2}$; Stark et al. 1992). The redshifts for the SIS and GIS become 0.007 and 0.018, respectively. These are consistent with the optical value of 0.0104, because the SIS and GIS have systematic gain uncertainties of $\pm 1\%$. The best-fit metal-abundances that are common to the two components are Si=1.6 (± 0.2), S=1.7 (± 0.2), Ar=2.0 (± 0.4), Ca=2.0 (± 0.5), and Fe=Ni=1.00 (± 0.07) in the solar unit. The Si and Fe abundance ratio, Si/Fe ~ 1.6 , is consistent with that of some other clusters having the similar ICM temperature of $\sim 4 \text{ keV}$ (Mushotzky et al. 1996; Fukazawa et al. 1998). When the abundance for each component was left free individually, the Fe (=Ni) abundances of the cool and the hot component were obtained to be 0.8 ($^{+0.7}_{-0.5}$) and 1.00 ($^{+0.16}_{-0.08}$) solar, respectively. All the other metal abundances were poorly constrained in this case, but at least have consistent values between the two components.

Previously, FABT94 reported that the two temperature model in which the cooler component has an significant excess absorption gives the best description to the SIS spectrum of the Cen cluster. However this could be caused by the systematic error in the SIS low-energy response (§5.2), which was not clearly known when FABT94 analyzed the data. In order to investigate this issue, we applied an additional absorption to the cool component. The model is expressed as WABS*(WABS*MEKAL+MEKAL+LINE), and referred to as Model 3. The fit with Model 3 (Figure 7c) reduced the minimum χ^2 by

only 1 from that with Model 2, and the excess absorption remained rather unconstrained; it is not statistically significant but can be as high as $2.6 \times 10^{21} \text{ cm}^{-2}$ at the cluster rest frame (90% upper limit). Therefore, the current datasets do not require an excess absorption for the cool component.

5.4. Cooling flow fits

In order to investigate other possible spectral models, we replaced the cool component with a cooling flow model without and with the excess absorption; they are respectively expressed as WABS*(MKCFLOW+MEKAL+LINE), referred to as Model 4, and WABS*(WABS*MKCFLOW+MEKAL+LINE), referred to as Model 5. Here MKCFLOW is the cooling flow model by Mushotzky & Szymkowiak (1988), employing the MEKAL model as a plasma emission code, in which the temperature is continuously distributed from the maximum temperature T_{max} to the minimum temperature T_{min} with emissivity inversely proportional to the cooling function at each temperature. We fix T_{min} at 0.2 keV, while we tie T_{max} to the hot component temperature.

The fit results are summarized in Table 3 and Figure 7d,e. Thus, neither Model 4 nor Model 5 gave acceptable fits, with significantly larger values of χ^2 than has been obtained with the two-temperature models. The most prominent discrepancy with the Model 4 is seen below 1 keV (Figure 7d). The discrepancy is somewhat relaxed with the Model 5 (Figure 7d), but it requires no Galactic absorption. Therefore the emission is unlikely to have such a multi-temperature structure as is predicted by the cooling flow hypothesis.

Judging from the most advanced observational information thus obtained through the simultaneous fits to the PSPC, SIS, and GIS spectra, the ICM in the central region of the Cen cluster can be regarded as consisting of the two distinct temperature components of ~ 1 keV and ~ 4 keV. This reconfirms the main conclusion obtained previously by FEA94, and justifies us to employ the two-temperature model rather than the cooling flow model.

6. Overall Spatial and Spectral Analysis

In order to unify the spatial results obtained in §4 and the spectral results derived in §5, in this section we quantify the overall ICM properties through a full forward-method analysis, considering simultaneously the spectroscopic and spatial dimensions. We start from a three-dimensional model cluster, which takes into account three important ingredients; the two-phase temperature structure, the double- β brightness distribution, and the central metallicity increase. We use the 1.6–10 keV GIS data and the 0.5–2.0 keV PSPC data. Although we do not use the SIS data explicitly for the reason described in §4.2, the analysis takes into account the spectral results obtained in § 5 for which the SIS data have significant contributions.

6.1. Method of analysis

We have sorted all the available GIS data of the Cen cluster into 10 spectra covering ten concentric annular regions, with outer boundaries at projected radii of 1', 2', 3'.5, 5', 6'.5, 8'.5, 11', 14', 18'.5 and 40'. These spectra are presented in Figure 8. Using predictions derived from a common model cluster, we attempt to fit jointly these 10 spectra as well as the $r = 0' - 120'$ PSPC radial profile (Figure 3). The fitting method is essentially the same as described in § 4, except that the GIS data mainly constrain the spectroscopic properties while the PSPC data strongly constrain the spatial properties.

According to the two-phase (two-temperature) modeling established in §5, we express the emissivity profile in a given energy range (E_1 to E_2) as

$$\epsilon(R; E_1, E_2) = Q_h(R) \cdot \Lambda(T_h, Z_h(R); E_1, E_2) + Q_c(R) \cdot \Lambda(T_c, Z_c; E_1, E_2) \quad , \quad (3)$$

where $Q(R)$ is the emission measure profile, Λ is the cooling function, and suffices c and h denote the cool and hot phases, respectively.

Following §4.4, we represent the emission measure profile of the hot phase, $Q_h(R)$, by a double- β model as

$$Q_h(R) = n_{0,1}^2 \left[1 + \left(\frac{R}{R_{c,1}} \right)^2 \right]^{-3\beta_1} + n_{0,2}^2 \left[1 + \left(\frac{R}{R_{c,2}} \right)^2 \right]^{-3\beta_2} \quad , \quad (4)$$

where $n_{0,1}$ and $n_{0,2}$ are model normalizations, having a dimension of plasma density, to be utilized in place of $\epsilon_{0,1}$ and $\epsilon_{0,2}$ of equation (2), respectively. For the cooling function Λ , we employ MEKAL model as has been used in the previous section. The hot-phase temperature T_h is assumed to be spatially constant, but left free to vary. We model the hot-phase metallicity profile $Z_h(R)$ as

$$Z_h(R) = \Delta Z \exp \left(-\frac{R}{R_Z} \right) + Z_0 \quad . \quad (5)$$

Here Z_0 is the outer-region metallicity, ΔZ is the central metallicity increment, and $R_Z > 0$ is the angular scale of the metallicity gradient, all of which are free parameters to be determined. We assume $Z_h(R)$ to be common to the two β -components of equation (4).

As to the cool phase, we model its radial emission measure profile, $Q_c(R)$, with a single- β model involving three free parameters, as

$$Q_c(R) = n_{0,c}^2 \left[1 + \left(\frac{R}{R_{c,c}} \right)^2 \right]^{-3\beta_c} \quad . \quad (6)$$

The cool-phase spectrum, $\Lambda(T_c, Z_c; E_1, E_2)$, is assumed to be spatially constant, with T_c and Z_c being the temperature and metallicity, respectively. We also introduce a cut-off radius, R_{cut} , beyond which there no longer exists the cool phase. From the *ROSAT* results (AF94), we fix $R_{\text{cut}} = 6'.0$.

The cluster model introduced here involves many free parameters. The hot component involves at least 10 free parameters, T_h , $n_{0,1}$, $n_{0,2}$, $R_{c,1}$, $R_{c,2}$, β_1 , β_2 , Z_0 , ΔZ , and R_Z . If the abundance ratios among the different elements are allowed to vary, the

number of free parameters becomes still larger. For the cool component there are at least 5 parameters, T_c , Z_c , $n_{0,c}$, $R_{c,c}$, and β_c , and even more if allowing variable abundance ratios. In addition, we leave free the relative normalization between the PSPC and the GIS, as well as the PSPC background which is assumed to be radius independent. Thus, the number of model free parameters becomes at least 17.

6.2. Results of the analysis

In actually fitting the 10 GIS spectra and one PSPC radial profile simultaneously with the cluster model described in §6.1, it is not practical to leave all the parameters free. Accordingly, we fix the chemical composition of the hot phase to obey the abundance ratios obtained with Model 2 in § 5.3, and model the iron abundance profile with equation (5), so that abundances of all the other heavy elements vary with R in proportion to that of iron. This leaves the hot phase with 10 free parameters. We also fix the temperature and various abundances of the cool phase (T_c , Z_c), and the hydrogen column density, all to the values derived with Model 2 in § 5.3. This also allows us to best utilize the SIS information, which is not incorporated directly here. Consequently, we have three free parameters specifying the cool component, $n_{0,c}$, $R_{c,c}$, and β_c . Adding the relative PSPC/GIS normalization and the PSPC background, the number of free parameters becomes 15.

By changing the 15 parameters and minimizing the chi-square, we search for the model which gives acceptable simultaneous fits to the 10 ring-sorted GIS spectra plus the PSPC radial profile. Then, as shown in Figure 9, an acceptable best-fit model has been obtained with $\chi^2/\nu = 377/405$. The best-fit parameters are summarized in Table 4, and the model emission measures of the hot and cool components and the hot-component iron-abundance profile are illustrated in Fig. 10.

The obtained hot-component temperature of $T_h = 3.9$ keV is somewhat lower than the value derived from the central $3'$ region (Table 3), possibly indicating a global outward temperature decrease in the hot component as has been observed in many clusters (Markevitch et al. 1998). However the difference is only 10%, so that we can safely regard the hot phase as being approximately isothermal. The wider-component parameters, $R_{c,1} = 7.5^{+2.1}_{-0.8}$ and $\beta_1 = 0.57^{+0.04}_{-0.02}$, are close to those derived in §4.3 using the $r = 6' - 120'$ *ROSAT* data. As shown in Table 4, the narrower-component parameters are poorly constrained. To assess the relative spatial scales between the two β components, we again performed the fit, forcing the narrower-component β value, β_2 , to be equal to that of the wider-component, β_1 . The derived core radii are $R_{c,1} = 9.6$ and $R_{c,2} = 2.3$ for the wider and narrower β components, respectively, with the common β of 0.59 and the relative normalizations of $n_{0,1}:n_{0,2}:n_{0,c}=1:3.9:16.4$, yielding a chi-square of $\chi^2/\nu = 380/406$. This agrees with the results in the double- β fits (Table 2). Also the values of $Z_0 = 0.2$, $\Delta Z = 1.5$, and $R_Z = 4.1$ are not much different from those found previously (e.g. FEA94; Ikebe 1995).

As to the cool-phase emission measure profile, $Q_c(R)$, the best-fit solution yields $R_{c,c} = 0.5^{+0.5}_{-0.3}$ and $\beta_c = 0.57^{+0.17}_{-0.11}$. Therefore $Q_c(R)$ is inferred to have a slightly smaller core radius than the narrower β -component describing $Q_h(R)$. In other words, the cool emission is somewhat more concentrated to the cluster center than the hard-band central excess emission.

Based on these results, we conclude that the two-phase model has been accepted by the *ASCA* and *ROSAT* data. Furthermore, the obtained parameters of the two-phase model are generally consistent with those obtained previously by FEA94, AF94, and Ikebe (1995).

6.3. Filling factor and the ICM mass distributions

In order to better illustrate the two-phase solution obtained in § 6.2, we introduce the volume filling factor $f(R)$ of the cool phase. We assume, after FEA94 and Ikebe (1995), that a local pressure balance is achieved between the two phases, i.e.,

$$n_c(R) T_c = n_h(R) T_h , \quad (7)$$

and the emission measure of the two phases can be expressed as

$$Q_h(R) = n_h(R)^2 \{1 - f(R)\} , \quad Q_c(R) = n_c(R)^2 f(R) . \quad (8)$$

Here $n_h(R)$ and $n_c(R)$ are densities of the hot and cool phase, respectively, and $f(R)$ is the volume filling factor of the cool phase. These two equations yield

$$f(R) = \left\{ 1 + \left(\frac{T_h}{T_c} \right)^2 \frac{Q_h(R)}{Q_c(R)} \right\}^{-1} . \quad (9)$$

We may then substitute the best-fit double- β model into $Q_h(R)$, and the best-fit single- β model into $Q_c(R)$, to obtain $f(R)$. The result is shown in Figure 11. Within $R = 60$ kpc, the average filling factor of the cool phase becomes 6–8%.

We may now substitute $f(R)$ back into equation (8), and convert the emission measure distributions into radial density distributions of the hot and cool components, n_h and n_c , respectively. The calculated ICM density distributions are shown in Figure 12. We can further calculate the mass profiles of the cool and hot ICM components as $\int 2\mu m_p n_c f dV$ and $\int 2\mu m_p n_h (1 - f) dV$, respectively, where μ is the mean molecular weight which is set to be 0.6, and m_p is the proton mass. We show the calculated ICM mass distributions in Figure 13a, together with the spherically integrated stellar mass distribution derived assuming the mass-to-light ratio of 8 from the optical brightness data of Schombert (1987) and Dickens et al. (1986). The integrated iron mass profiles in the cool and hot phase were also calculated and illustrated in Fig. 13b.

6.4. The gravitating mass distribution

Using the best-fit two-phase model, we also calculated the radial profile of the total gravitating mass, M_{tot} , as

$$M_{\text{tot}}(R) = - \frac{R^2}{\rho_g G} \frac{dP}{dR} , \quad (10)$$

where P is the ICM pressure, ρ_g is the mass density of ICM, and G is the constant of gravity. This equation is based on the standard formula for an isothermal ICM in hydrostatic equilibrium (e.g. Sarazin 1988). The pressure P is given as $P = 2n_c k_B T_c =$

$2n_h k_B T_h$ (k_B is the Boltzmann constant), while the gas mass density ρ_g can be expressed as

$$\rho_g = 2\mu m_p \{f n_c + (1 - f)n_h\} . \quad (11)$$

The calculated $M_{\text{tot}}(R)$ is shown in Figure 13c. There, we also present dark-matter distribution, $M_{\text{DM}}(R)$, derived by subtracting the ICM mass and the stellar mass from $M_{\text{tot}}(R)$. $M_{\text{tot}}(R)$ agrees quite well with the result by AF94, except in the central region where the two-phases are coexisting. Figure 13d gives the R -dependence of the baryon fraction, i.e. the stellar mass plus ICM mass normalized to the total mass.

In Figure 13c, both $M_{\text{tot}}(R)$ and $M_{\text{DM}}(R)$ exhibit a shoulder-like feature at $R \sim 80$ kpc. This feature arises through the following two effects. One is that the emissivity profile requires two β components even in the high energy range, as shown in § 4.4 and § 6.2. Therefore, the gravitational potential must exhibit an additional drop within ~ 80 kpc, in order to confine the excess ICM. The other is that the central excess in n_h (the gas density of the hot component, hence pressure) is in fact still more prominent than that seen in $\epsilon_h(R)$ or $Q_h(R)$, because of the $(1 - f)$ factor in equation (8). In other words, the central excess is expected to be less prominent in the hard-band emissivity (or emission measure) than in the hot-phase pressure, because the hot phase is partly displaced by the cool phase near the cluster center. A further discussion is given in § 7.2.

7. Summary and Discussion

7.1. Summary of results

We have analyzed the most advanced X-ray data of the Centaurus cluster obtained with the *ROSAT* PSPC, the *ASCA* GIS, and the *ASCA* SIS. In § 4, we showed that the radial count-rate profiles in several broad energy bands obtained with the GIS and the PSPC are described adequately with the double- β models (Figure 3c & 2c, Table 2). This means that the central excess brightness within $R \sim 6'$ that has been known in soft X-rays is present over the entire *ASCA* energy range up to 10 keV, although the excess fraction is lower in higher energies (Figure 4). The “deprojected” six-band spectrum at the center (Figure 5) is clearly non-isothermal, indicating a multi-phase property. This implies that the single-phase approximation that was often used to describe soft X-ray results on clusters is no longer valid at least for the Cen cluster.

In §5, we jointly analyzed the X-ray energy spectra taken with the PSPC, GIS, and SIS, and showed that the two-temperature (~ 1 keV and ~ 4 keV) thermal-emission model modified by the Galactic absorption gives the best description of the spectra, reconfirming the main conclusion of the previous work by FEA94. The spectra did not require significant excess absorption to the cool component. The cooling flow model, either with or without the excess absorption, did not give acceptable fits to the spectra.

Combining the spatial and spectral properties derived respectively in §4 and §5, we have obtained in §6 the overall ICM model by simultaneously fitting the ring-sorted GIS spectra and the PSPC radial profile. The best-fit solution indicates that, within $\sim 6'$ (~ 100 kpc) of the cD galaxy NGC 4696, the ICM can be regarded as an unresolved mixture of two disjoint phases; a hot phase with $T_h \sim 4$ keV of which the emission measure profile can be expressed by a double- β model with core radii ~ 175 kpc and

~ 43 kpc, and a cool phase with $T_c \sim 1$ keV of which the emission measure profile is described by a single- β model having a small core radius of ~ 10 kpc. The dramatic metallicity increase near the center, first revealed by FEA94, has also been confirmed. We summarize the characteristics of the two phases in Table 5.

These results consistently indicate that the central region within $R \sim 3'$ (50 kpc) of the Cen cluster is a site of three characteristic phenomena. One is the hard X-ray excess emissivity, revealed in § 4.3 and reconfirmed in § 6.2. Another is the co-existence of the hot and cool phases, with the cool-phase filling factor behaving as shown in Figure 11. The other is the high metallicity in both phases, as shown in § 5.3 and Figure 10.

7.2. Dark matter distribution

The two-phase modeling of the Cen cluster ICM has yielded the integrated mass distributions as shown in Figure 13c (§6.4). At $R \sim 80$ kpc, the total mass curve exhibits a characteristic bending feature. Although details of this feature may depend on the ICM modeling, the deviation from a King-type profile is a robust result, because it directly results from the central hard X-ray excess above the single- β model (§ 4.3). In other words, the potential profile of the Centaurus cluster becomes deeper at the center than a King-type one that has a flat core, and this deepening causes the central excess brightness in hard X-rays. In soft X-rays, the central excess emission is enhanced by the cool phase.

As seen from Figure 13d, this central mass excess is significantly contributed by the stellar mass in the cD galaxy. Nevertheless, even after subtracting the stellar mass contribution, the dark matter profile (Figure 13c) still appears to show an inflection point at $R \sim 80$ kpc as the total mass profile. Therefore, the dark matter distribution itself is inferred to deviate from a King-type profile.

Such a central excess in the dark-matter distribution has been observed in the Fornax cluster (Makishima 1995; Ikebe 1995; Ikebe et al. 1996), Abell 1795 (Xu et al. 1998), the elliptical galaxy NGC 4636 (Matsushita et al. 1998), and several galaxy groups (Mulchaey & Zabludoff 1998). These dark matter profiles have been interpreted as representing a galaxy/cluster hierarchy; the dark matter is clustering on two separate spatial scales corresponding to the central galaxy and the entire cluster. The effect is above all evident in the Fornax cluster (Ikebe et al. 1996), since the X-ray peak associated with the cD galaxy, NGC 1399, is offset by 40–50 kpc from the center of the cluster emission. Furthermore in NGC 4636, the presence of two separate spatial scales has been confirmed in a model independent manner by Matsushita et al. (1998). Then, the dark matter in the Cen cluster may also show such a dual distribution.

Alternatively, this dual structure may be an artifact caused by our particular modeling using two β -models, and the dark matter may distribute on a single spatial scale with a central cusp. In fact, such a cuspy distribution of dark matter, called *universal density profile*, has been proposed by Navarro, Frenk, & White (1996, 1997: hereafter NFW model) based on N -body simulations. The NFW model describes the dark-matter density profile as

$$\rho(R) = \rho_c \delta_c \left(\frac{R}{R_s} \right)^{-1} \left(1 + \frac{R}{R_s} \right)^{-2}, \quad (12)$$

where ρ_c is the critical density that is a constant, δ_c is a characteristic density, and R_s is a scale radius. Its integral form becomes (Suto, Sasaki, & Makino 1999)

$$M_{\text{DM}}(R) = 4\pi\rho_c\delta_c R_s^3 \left\{ \ln \left(1 + \frac{R}{R_s} \right) - \frac{R/R_s}{1 + R/R_s} \right\}. \quad (13)$$

When an isothermal ICM is hydrostatically confined in the gravitational potential corresponding to equation (12) or equation (13), the gas density profile is expressed as (Makino, Suto, & Sasaki 1998)

$$n(R) = n_0 \left(1 + \frac{R}{R_s} \right)^{\frac{BR_s}{R}}, \quad (14)$$

where n_0 and B are parameters related to the central ICM density and the ICM temperature, respectively. Actually, Tamura (1998) has shown that the *ASCA* and *ROSAT* data of the Abell 1060 cluster can be explained by a nearly isothermal ICM confined in the NFW-type potential (possibly with an even steeper cusp).

In order to examine the interpretation in terms of the NFW model, we again perform a simultaneous fitting to the PSPC and GIS data, with an alternative two-phase ICM model. In § 6 we modeled the two emission-measure profiles, $Q_h(R)$ and $Q_c(R)$, and then simulated the data. Here we take a somewhat different approach; while we model $Q_c(R)$ again in terms of a single- β model via equation (6) as before, we specify the total mass profile instead of $Q_h(R)$. Specifically, we express the total mass profile as a sum of the stellar mass profile $M_*(R)$, and the NFW dark-matter profile M_{DM} given by equation (13). This is because the NFW model neglects the baryonic contribution. We fix $M_*(R)$ according to Figure 13a, while we treat δ_c and R_s in equation (13) as fitting parameters. We further assume, as in § 6, that the hot phase is isothermal, the cool and hot phases are in pressure balance, and the cool component is distributed up to $6'$ from the center. Then, in the outer region of $R > 6'$ where the cool phase and the stellar mass are both negligible, the hot-phase density profile $n_h(R)$ can be given analytically by equation (14). In contrast, within $R = 6'$ where $n_h(R)$ is affected by the cool phase and the stellar mass, we must numerically solve the ordinary differential equation for $n_h(R)$ as

$$\frac{dn_h(R)}{dR} = -\frac{\mu m_p G}{k_B T_h} \left\{ \frac{T_c}{T_h} \left(1 - \frac{T_c}{T_h} \right) \frac{Q_c(R)}{n_h(R)} + n_h(R) \right\} \frac{M_*(R) + M_{\text{DM}}(R)}{R^2}, \quad (15)$$

once $Q_c(R)$, $M_*(R)$, and $M_{\text{DM}}(R)$ are specified. This relation refers to equation(10), into which equations (7) through (11) have been substituted.

With this alternative ICM model, we have fitted the GIS spectra and the PSPC profile simultaneously as was performed in § 6. The hot phase temperature was left free to vary, while the hot-phase metallicity profile was again modeled with equation (5). The cool-phase temperature and the cool-phase metallicity were fixed to the values derived with Model 2 in § 5.3; so was the overall hydrogen column density. This has given an acceptable fit to the GIS/PSPC data, with a reduced chi-square of $\chi^2/\nu=400/408$ (to be compared with $\chi^2/\nu = 377/404$ derived in § 6.2 using the double- β modeling). The best-fit parameters are given in Table 6 and the model profiles are illustrated in Figure 14. Although we treated both the scale radius (R_s) and the characteristic density (δ_c) as free parameters, the NFW model indicates that they are correlated in such a way that central densities are higher in lower mass systems (Navvaro, Frenk, & White

1996). In order to examine the NFW-model fit result for the mass-density relation, we calculated the virial mass, M_{200} , which is the total mass within the sphere encompassing a mean overdensity of 200. The derived virial mass is $3.7 \times 10^{14} M_{\odot}$ for $H_0 = 50$, or $1.6 \times 10^{14} M_{\odot}$ for $H_0 = 75$, which agree with the mass-density ($M_{200} - \delta_c$) relations derived with SCDM ($\Omega_0=1$, $H_0=50$) or CDMA ($\Omega_0=0.25$, $H_0=75$) cosmological models, respectively (for detail see Navvaro, Frenk, & White 1997). Therefore, the dark-matter density profile of the Cen cluster is concluded to be consistent with the NFW model.

For comparison, we also tried a King-type profile for the dark matter distribution, instead of the NFW profile. In this case, we substitute into equation (15)

$$M_{\text{DM}}(R) = \frac{3\beta' k_B T_h}{\mu m_p G} \frac{R^3}{R^2 + R_c'^2} \quad , \quad (16)$$

where the hot component temperature T_h , the core radius R_c' , and β' are free parameters. In the outer cluster region where the temperature structure becomes isothermal and the stellar mass contribution is negligible, the ICM density profile is expressed with a β -profile as

$$n(R) = n_0 \left\{ 1 + \left(\frac{R}{R_c'} \right)^2 \right\}^{-\frac{3}{2}\beta'} \quad , \quad (17)$$

instead of equation (14). The fit with the King-type profile yielded a minimum chi-square value of $\chi^2/\nu=428/408$ (Table 6), which is significantly worse than that with the NFW mass model. As illustrated in Figure 14a, the best-fit King-type profile is less massive than the NFW profile in the central region.

These results confirm that the dark matter mass profile in the Cen cluster indeed deviates from a King-type one, exhibiting a significant central excess. In other words, the central excess in the total mass distribution, which we have discovered, cannot be attributed entirely to the contribution of stellar mass in the cD galaxy. The excess dark matter can be reproduced with the single NFW profile; then, the double- β modeling we used in § 4 and § 6 may be regarded as a conventional one rather than a physical one. Of course, there still remains the alternative possibility that the dark-matter distribution in the central region in fact has two distinct spatial scales, like in the Fornax cluster; in that case, the double- β modeling has a physical meaning. In short, the central excess in the total mass profile consists of a baryonic component and a dark component. The latter, in turn, is either a dark halo associated with NGC 4696, or a central cusp in the cluster-scale dark matter distribution. With the current datasets alone, we cannot distinguish these two alternatives.

7.3. Nature of the central cool phase

Our results indicate that the central volume of the Cen cluster is permeated by the hot-phase ICM, where a small amount of cool phase is mixed up. The cool phase, having an average filling factor of 6–8% within 60 kpc, presumably takes the form of blobs or filaments immersed in the hot phase on angular scales too small to be resolved with *ASCA*. Indeed, the *ROSAT* HRI observations of some cD clusters have revealed evidence of small-scale (a few kiloparsec) X-ray inhomogeneities (Sarazin, O’Connell, & McNamara 1992ab; Prestwitt et al. 1995). Then, what is the nature of the cool

phase? The failure of the cooling-flow model (§ 5.4) inspires us to explore an alternative interpretation.

First of all, the cool phase has a temperature of $T_c = 1.4$ keV, and a core radius of $5 - 27$ kpc centered on the cD galaxy. These values are similar to, or slightly higher (larger) than, those of inter-stellar medium (ISM) of ordinary elliptical galaxies (e.g. Forman, Jones, & Tucker 1985; Awaki et al. 1994; Matsumoto et al. 1997). It is hence suggested that the cool phase has a close connection to the ISM of the cD galaxy (FEA94; Makishima 1994, 1996b, 1997). Furthermore, the value of T_c is comparable to the virial temperature of the central dimple in the gravitational potential.

Employing the two-phase picture together with equations (7) and (8), and assuming the cool-phase abundance of 1.0 solar, the total emission integral and total mass of the cool phase are calculated to be $6 \times 10^{65} \text{ cm}^{-3}$ and $(4 - 5) \times 10^{10} M_\odot$, respectively. (Note that the cool-phase mass derived in FEA94, $(1 - 2) \times 10^{11} M_\odot$, was subject to a trivial mistake.) These values are comparable to those of the ISM associated with the most luminous non-cD elliptical galaxies (Forman et al. 1985; Matsushita 1997). As a consequence, the cool phase of the Cen cluster lies on a smooth extension of the temperature vs. emission-integral relation or temperature vs. gas-mass relation seen among non-cD elliptical galaxies (Matsumoto et al. 1997; Matsushita 1997). The ratio of the cool-phase mass to the stellar mass of NGC 4696 is $2.0 - 2.5\%$, which is also comparable to those of non-cD elliptical galaxies (Forman et al. 1985). Therefore, the cool phase may be regarded essentially as the ISM of the cD galaxy.

In comparison with the ISM of the most X-ray luminous non-cD ellipticals, which is thought to have a filling factor of $f \sim 1$, the cool phase of the Cen cluster may have a similar gas mass and a similar spatial extent with $f \sim 0.07$ on average. Then, we expect the cool phase of the Cen cluster to be $0.07^{-1} \sim 14$ times more luminous than the ISM of non-cD ellipticals. Actually, the $0.5-4$ keV luminosity of the cool phase of the Cen cluster, $1.1 \times 10^{43} \text{ erg s}^{-1}$, is some 10 times higher than those of the most X-ray luminous ordinary elliptical galaxies (e.g. Forman et al. 1985), in good agreement with the above prediction.

In § 5.3, we have determined the iron abundance of the cool phase to be ~ 1.0 solar. This should be compared with ISM metallicity of non-cD elliptical galaxies. Through observations with *ROSAT* (Forman et al. 1993), *BBXRT* (Serlemitsos et al. 1993), and *ASCA* (Awaki et al. 1994; Loewenstein et al. 1994; Matsumoto et al. 1997), the ISM of elliptical galaxies were found to be extremely metal poor. This was a serious theoretical problem, because the measured ISM abundances, often below half a solar, fall even below those implied by the contribution from stellar mass loss, leaving essentially no room for the supernova contribution (Arimoto et al. 1997). However, the detailed recent work by Matsushita (1997) and Matsushita et al. (1997) clearly indicates that the most X-ray luminous ellipticals have the ISM abundances of $0.7-1.0$ solar, in agreement with those from the stellar mass-loss. Then, the cool-phase metal-abundance of the Cen cluster that we measured is close to, or only slightly higher than, those of the most X-ray luminous non-cD ellipticals.

Thus, from every aspect including the temperature, angular extent, mass, and metallicity, the cool phase of the Cen cluster can be regarded as the ISM associated with the cD galaxy, NGC 4696, which is among the most luminous ellipticals. The only basic difference is that the ISM of NGC 4696 is confined not only by the central potential drop

but also by external pressure from the surrounding hot phase to achieve the considerably low filling factor, hence the higher density and the higher luminosity, than those of ordinary ellipticals.

7.4. Origin of the metallicity increase

Although the increased metallicity in the cool phase has been explained successfully in § 7.3 using analogy to the ISM of ordinary ellipticals, we must also explain the iron concentration seen in the hot phase. Indeed, the metallicity increase in the central part of the hot phase is even more robust than the abundance enrichment in the cool phase, because the former can be directly evidenced by the central increase in the Fe-K line equivalent width. Such an effect is not limited to the Cen cluster, because cD clusters generally exhibit statistically significant metallicity increases at the center (Fukazawa 1997).

Obviously, the metals in the ICM must have been supplied by individual stars in the member galaxies, as clearly demonstrated by the large-scale abundance gradient found by Ezawa et al. (1997) from the AWM7 cluster. Therefore, a comparison between the spatial distribution of the iron mass and the optical light profile is crucial. In Figure 15, we plot iron-mass to light ratio (IMLR; Ciotti et al. 1991), i.e. ratio of the total iron mass (contained in both ICM phases) within each radius to the total optical luminosity within the same radius, expressed in solar units.

The plot clearly reveals an outward increase in the IMLR, until it reaches ~ 0.01 (at ~ 400 kpc) which is a typical IMLR found in clusters of galaxies (Ciotti et al. 1991; Arnaud et al. 1991; Tsuru 1992; Renzini et al. 1993; Renzini 1997). In other words, the iron is more widely spread than the stars contrary to the impression we get from the measured steep metal profile, while the iron is more concentrated than the ICM mass profile as evidenced by the strong central metallicity enhancement. Actually, another two-phase model, in which the constant IMLR is assumed rather than equation (5) is adopted, gave a significantly worse fit to the GIS+PSPC data with $\chi^2/\nu=464/407$, because it predicts the iron concentration much stronger than is observed. Note that this argument utilizes only the observed quantities, and unaffected by uncertainties in the supernova rate or its time evolution.

Reisenegger et al. (1996) argued that the central metallicity increase, produced by the cD galaxy, may be reduced by the cooling flow, because the metal-rich plasma is swept inwards and then disappears. However, the value of $R_Z \sim 4'$ (Table 4) we have obtained is significantly larger than the scale length of the metallicity increase, $\sim 2'$, calculated by Reisenegger et al. (1996). (Note that the instrumental effects have already been removed from R_Z .) Furthermore, the prediction by Reisenegger et al. (1996), that the CF rate should negatively correlate with the metal concentration scaled to the stellar mass of the cD galaxy, has not been confirmed in a sample of poor clusters observed with *ASCA* (Tamura et al. 1996). Therefore, the outward increase in IMLR need to be explained by some mechanism other than the CF: there are the following two possible mechanisms.

First, the supernova ejecta may be so energetic that they may not be confined by the gravitational potential of NGC 4696. As a supporting evidence, we refer to a large

number of IMLR measurements in clusters, groups, and elliptical galaxies (Ciotti et al. 1991; Arnaud et al. 1991; Tsuru 1992; Renzini et al. 1993; Renzini 1997; Matsushita 1997). For clusters having the X-ray temperature higher than ~ 1 keV, the IMLR integrated over the whole system is remarkably constant at ~ 0.02 . On the contrary, the IMLR of systems that have temperature less than ~ 1 keV is significantly lower on average, and scatters widely. As the above authors argue, these results indicate that the metal-rich gas escapes significantly from smaller systems, such as groups and single elliptical galaxies, because their gravitational potential is not deep enough. Then, a considerable fraction of the supernova products in NGC 4696 may well have escaped from its gravitational potential in the form of winds, to spread over the cluster space.

In addition, motion of the cD galaxy can also contribute to the metal spread-out. Although NGC 4696 now seems to sit at the bottom of the cluster potential, it may have been moving through the cluster space and gradually became stationary over its lifetime. Then, the metal-enriched supernova products may have been continually spilling over the galaxy potential, or stripped off the host galaxy by ram pressure exerted from the ICM, to be left over in the surrounding ICM as the galaxy moves away. Actually, the position of a cD galaxy, which generally coincides with the X-ray peak position, is often displaced from the centroid of the large scale X-ray emission (e.g. Ikebe et al. 1996; Neumann & Böhringer 1995; Lazzati & Chincarini 1998). Offsets are seen also between the radial velocities of the central galaxies and the average velocities of the member galaxies (e.g. Beers & Geller 1983; Zabludoff, Huchra, & Geller 1990; Zabludoff et al. 1993). This suggests that the central galaxy is in an harmonic oscillation mode within the central potential minimum (Lazzati & Chincarini 1998), or that the central potential structure itself is still evolving with time.

From these considerations, we can interpret that the excess iron in the central region of the Cen cluster was actually produced by the cD galaxy over the Hubble time, and transported to a wider cluster space.

7.5. Radiative cooling

We have so far argued that the cool phase is essentially the ISM associated with the cD galaxy. However, our two-phase solution implies the central plasma densities of $\sim 2 \times 10^{-2}$ and $\sim 6 \times 10^{-2} \text{ cm}^{-3}$, hence radiative cooling times of ~ 1 Gyr and $\sim 8 \times 10^7$ yr, for the hot and cool phases respectively (both assuming 1 solar abundance). Thus, the cool phase would be subject to a strong radiative cooling; the stable presence of such a plasma component must be explained.

Before attempting to solve this problem, let us consider ISM of non-cD elliptical galaxies. In many elliptical galaxies, the ISM has been observed to be hotter than the stellar kinetic temperature by up to a factor of ~ 2 (Matsumoto et al. 1997; Matsushita 1997). Therefore, the presence of some ubiquitous ISM heating mechanism is indicated. This tendency becomes more prominent in X-ray fainter ellipticals (Matsumoto et al. 1997), presumably because the heat input is less diluted and the ISM cooling effect becomes less important in the X-ray fainter galaxies, which have smaller amount of ISM. At the same time, the measured ISM metal abundances clearly decrease towards X-ray fainter ellipticals (Matsumoto et al. 1997; Matsushita 1997). Therefore, the supernova heating cannot be the main mechanism of the ISM heating.

We presume that the ISM is heated by random stellar motion in each galaxy, through amplification of interstellar magnetic fields. The fields will in turn reconnect to heat up the ISM, in particular near the magnetopause of each star. Quantitatively, the random stellar motion in giant elliptical galaxies has a total kinetic energy of $(0.1 - 1) \times 10^{60}$ ergs. If a few tens percent of this energy is spent in the ISM heating over the Hubble time, we can expect a heating luminosity up to a few times 10^{41} ergs s^{-1} , which is comparable to the observed X-ray luminosities of elliptical galaxies. As argued by Kritsuk (1992, 1996, 1997), this heating mechanism may balance the radiative cooling of the ISM, and keep the ISM in an apparent steady state. (Microscopically, the ISM may recycle between the cooling and heating stages.) This scenario is best supported by the observational fact that the ISM emissivity is spatially proportional to the stellar light density (Forman, Jones, & Tucker 1985), the latter being proportional to the local heat input.

If we apply the same idea to the cool phase of the Cen cluster, its high luminosity (1×10^{43} ergs s^{-1}) requires that nearly all the stellar kinetic energy of NGC 4696 has been released in the plasma heating. In other words, we must invoke a significant dynamical evolution of NGC 4696. This is actually quite plausible, because NGC 4696, being a cD galaxy, must have grown up via cannibalism. Conversely, the merger process would not proceed without such energy dissipation, and the plasma heating is one of the most plausible dissipation mechanisms. Suppose that the stellar mass of NGC 4696 has doubled to the present value by repeated mergers of dwarf galaxies over the Hubble time. The total energy release will be $\sim 1 \times 10^{42}$ ergs s^{-1} if the infalling dwarf galaxies are assumed to have no dark-matter halos. When the dwarfs are thought to have mass-to-luminosity ratios similar to that of the present-day NGC 4696, the energy release will be ~ 5 times larger. Then, we expect an average heating luminosity in the range $(1 - 5) \times 10^{42}$ ergs s^{-1} , which may be sufficient to sustain the cool-phase luminosity.

Finally, we must consider the spatial configuration of the cool and hot phases. If they were not thermally insulated from each other, the cool phase would be heated up and disappear quickly by conductive heat flux from the hot phase (Takahara, & Takahara 1979). Therefore, the two phases must be thermally insulated from each other, presumably by magnetic fields. For example, the cool phase may fill up the interior of numerous magnetic loops anchored to the cD galaxy (Makishima 1997), whereas the hot phase may permeate the open-field regions which connect to the outer cluster space. The heating process considered above in principle operates on both phases, but it must be much more effective on the cool phase due to the higher field strengths inside each magnetic loop and due to the closed magnetic configuration. Any heating effect on the hot phase would be difficult to observe, because the heat deposit would be quickly transported to the outer region by the heat conduction within the hot phase, with a typical time scale of $\sim 10^7$ yr.

In summary, by invoking the merger process, magnetic reconnection, and a certain magnetic configuration, we can at least qualitatively give a self-consistent account of the two-phase nature observed in the central region of the Cen cluster.

We are grateful to Professor J. Trümper and the ROSAT team for support and providing us with the *ROSAT* All Sky Survey data. We also thank H. Böhringer and T. Reiprich for discussion and helping the *ROSAT* data analysis. We appreciate the *ASCA* team for operating the spacecraft and supporting the data analysis. Y.I. is supported by

the post-doctoral program of Max-Planck Gesellschaft. K.Matsushita is supported by the post-doctoral program of Japan Society for the Promotion of Science.

Fig. 1.— (a) Field of view of GIS2 and GIS3 for the four pointing positions used in the analysis. (b) The 0.7-10 keV X-ray intensity contour of the Centaurus cluster derived from the GIS data. The background is subtracted. A structure seen at (12^h50^m, -41°23') is an artifact due to synthesizing the data from the four pointings with the exposure correction but without the vignetting correction.

Fig. 2.— (a) The *ASCA* GIS radial count-rate profiles in five energy bands; 1.6–2.4 keV, 2.4–4.5 keV, 4.5–6.0 keV, 6.0–7.1 keV, and 7.1–10 keV. The background is subtracted. (b) The residuals of the single- β model fits to the GIS radial count-rate profiles. (c) The residuals of the double- β model fits to the radial count-rate profiles. The fit parameters refer to Table 2.

Fig. 3.— The *ROSAT* PSPC radial count-rate profile in the 0.5-2.0 keV band. The background is included. (a) The single β -model fits to the PSPC radial count-rate profile of the whole 0 – 120′ region and (b) of the 6′ – 120′ region. (c) The double β -model fit to the PSPC radial count-rate profile. The fit parameters refer to Table 2. In the fits, a constant but free background is added.

Fig. 4.— Relative central excess (see text) in the six energy bands. The vertical bars represent 90% ($\Delta\chi^2=2.706$) errors.

Fig. 5.— Deprojected energy spectrum for the central spherical region of $R < 1.5'$ (diamonds). Energy spectra predicted by the plasma emission models of temperature 1 keV and 4 keV are also illustrated with the solid and dashed histograms, respectively. The Raymond-Smith code is used assuming a red-shift of 0.0104, a metallicity of 1.0 solar, and the Galactic absorption of $8.8 \times 10^{20} \text{ cm}^{-2}$.

Fig. 6.— The PSPC (asterisks), GIS (open circles), and SIS (crosses) spectra in the central 3 arcmin region.

Fig. 7.— The fit residuals to the spectra of Figure 6 with (a) Model 1, (b) Model 2, (c) Model 3, (d) Model 4, and (e) Model 5. Parameters are given in Table 3.

Fig. 8.— The 0.7–10 keV GIS spectra extracted from the 10 annular regions. Outer radii used to extract the spectra are (a) 1', (b) 2', (c) 3'.5, (d) 5', (e) 6'.5, (f) 8'.5, (g) 11', (h) 14', (i) 18'.5, and (j) 40'.

Fig. 9.— The simultaneous fit to the 10 GIS annular spectra (a-j: the same as figure 8) and the PSPC radial profile (k) with the two-phase model. The energy ranges used for the fit are 0.5–2 keV and 1.6–10 keV for the PSPC and GIS data, respectively. Crosses show the data, and solid histograms show the fitted models convolved with the responses of the X-ray telescopes and the detectors. Three components in the model, i.e. the hot component, the cool component, and the background, are also illustrated with dotted histograms, dashed histograms, and dot-dashed histograms, respectively. In panel (k), the two β components constituting the hot-phase emission are drawn separately.

Fig. 10.— (a) The emission measure profiles of the hot (solid lines) and cool (dashed lines) component, and (b) the iron abundance profile derived from the two-phase model fit. Thick lines show the best fit models, while thin lines indicate extreme cases that produce a $\Delta\chi^2 = 2.706$ corresponding to the 90% confidence limit.

Fig. 11.— Radial profiles of the filling factor of the cool phase. The thick line and the thin lines represent the same cases as described in Fig. 10.

Fig. 12.— Radial profiles of the electron densities of the hot (solid lines) and cool components (dashed lines). The thick line and the thin lines represent the same cases as described in Fig. 10.

Fig. 13.— (a) The integrated radial mass profiles of the ICM in the hot (solid lines) and cool (dashed lines) phases, shown together with the stellar-component mass (dotted line). (b) The integrated iron mass in the hot (solid lines) and cool (dashed lines) phases. (c) The integrated mass of the total gravitating matter (solid lines) and the dark matter (dashed lines). (d) The baryon fraction. In the all panels, the thick line shows the best-fit model, while thin lines show extreme cases within 90% ($\Delta\chi^2=2.706$) confidence limits.

Fig. 14.— The best-fit solutions in terms of the Navarro, Frenk, & White model (bold lines) and the King-type model (thin lines). (a) The dark matter profiles. The stellar mass is also plotted with the dashed line. (b) The emission measure profiles of the hot (solid lines) and the cool (dashed lines) phases. (c) The filling factor of the cool phase calculated from the best-fit model.

Fig. 15.— The Iron Mass to Light Ratio derived with the 2-phase model fit. The thick line shows the best-fit model, while thin lines show extreme cases within 90% ($\Delta\chi^2=2.706$) confidence limits.
